Penile Mass in a Dog

Mark Morton, DVM
Lisa Pohlman, DVM, MS, DACVP
Kansas State University

A 2-year-old, castrated retriever crossbreed presented with a history of hemorrhagic discharge from the prepuce.

History
The dog was adopted from a shelter approximately 18 months before presentation; prior history was unknown. Approximately 3 months before presentation, the dog began to have hemorrhagic discharge from the prepuce. There was no evidence of hematuria, stranguria, or other urinary abnormalities. The patient’s appetite, activity level, and attitude remained normal, and the clients had not noticed any other abnormalities.

Examination
The dog was bright and alert at presentation. Temperature, pulse, and respiratory rate were within normal limits. On palpation of the prepuce, a solitary mass was discovered at the base of the penis. Extension of the penis from the prepuce revealed a lobulated, ulcerated, friable, and hemorrhagic mass of approximately 3 cm × 2 cm (Figure 1). There were no other clinically significant findings. An impression smear was submitted for cytological evaluation (Figure 2, next page).

Cytologic Description
The impression smears (Figures 2–5, next page) were of high nucleated cellularity with scattered RBCs in the background. Most nucleated cells were round cells with rounded, eccentrically placed nuclei with a coarse chromatin pattern and prominent, sometimes multiple, nucleoli. Cytoplasms were basophilic and occasionally contained discrete small vacuoles. Anisocytosis and anisokaryosis were mild. Mitotic figures were scattered. Occasional neutrophils and eosinophils and rare macrophages were seen among neoplastic cells.

1. Would you categorize the predominant population of cells as round, spindle, or epithelial?

2. What other cytologic features (e.g., chromatin, cytoplasmic features) in this predominant population help specifically identify the lesion?

3. Which are the mitotic figures? What is their prognostic significance in this lesion?

The TVT cells have eccentrically placed nuclei that have a coarse chromatin pattern and prominent, sometimes multiple, nucleoli. Cytoplasmic basophilic and sometimes contain discrete small vacuoles. Mitotic figures (red arrows), neutrophils (black arrow), eosinophils (yellow arrows), and macrophages (green arrows) are evident. RBCs are scattered in the background. (Modified Wright's stain, 600× original magnification)

Note the characteristic discrete, cytoplasmic vacuoles (pink arrowheads) and prominent nucleoli (black arrowheads) of the TVT cells. Mitotic figures (red arrows), eosinophils (yellow arrow), and macrophages (green arrow) are evident. (Modified Wright's stain, 1000× original magnification)

The FRONTLINE® Plus Premium Pack is filled with added value your clients can get only through you.

Inside for your clients:

• 3 or 6 doses of FRONTLINE Plus
• SATISFACTION PLUS GUARANTEE™*
• Money-saving coupon
• Pet Health Guide
• A PIN code for a free 5”x7” Snapfish Soft Cover Photo Book**

* The guarantee offers your choice of a refund, product replacement, or a FREE in-home inspection and treatment, if necessary. Please see full details at www.FRONTLINE.com

** Pet owner pays for shipping & handling.
Diagnosis
Transmissible Venereal Tumor (TVT)

TVT is a transplantable and contagious neoplasm of dogs that is transferred easily via direct contact of neoplasm to mucosa during mating or licking, which results in transplantation of tumor cells. The most common site for this tumor is external genitalia; however, lesions can be found on the face, nose, and nasal passages (ie, from sniffing and licking). TVTs are most commonly seen in patients from tropical areas with many free-roaming dogs; scattered pockets of disease are seen in the United States. The author has recently diagnosed several cases of TVT in which none of the dogs had a known history of travel outside of Kansas, and all were adopted from Kansas shelters.

Classic TVT signs include genital, facial, or nasal masses (any size; may be friable, ulcerated) with no other physical abnormalities. If the mass on the genitals is large enough, it can cause hematuria, dysuria, or excessive licking. In patients with a competent immune system, the tumor is typically benign and often regresses spontaneously. Malignant TVTs have been reported; however, it is estimated that less than 10% of TVTs metastasize. Various sites of metastasis have been reported (eg, lymph nodes, subcutaneous tissue, skin, spleen, tonsils, liver, eyes, oral mucosa, pituitary gland, peritoneum, brain, bone marrow).

Cytology & Diagnosis
A diagnosis of TVT can usually be made via cytologic preparation, as TVT cells have a distinct cytologic appearance. Smears are usually highly cellular and composed of large round cells that have an eccentrically placed nucleus containing granular chromatin and a single, often prominent nucleolus. The cytoplasm is pale blue and does not contain granules, but cytoplasmic vacuoles are typical. Mitoses may be common. If present, abnormal mitotic figures are not prognostic of biologic behavior of the tumor. Small mature lymphocytes are often seen, especially if the tumor is regressing. Many of these tumors are ulcerated, so surface impression smears or swabs may contain numerous inflammatory cells with bacteria.

Treatment & Prognosis
Although tumors may regress, treatment is highly recommended because of the contagious nature and potential complications of secondary infection, stranguria, or dysuria. Chemotherapy with vincristine is preferred for 2 weeks beyond resolution. A CBC is performed before every treatment to monitor neutrophil counts. If the total neutrophil count is less than 3000 cells/µL, the treatment is delayed. If the neutrophil count is lower than 1500 cells/µL and the patient is otherwise normal, an oral broad-spectrum antibiotic could be used to prevent secondary infection. Hospitalization, IV fluids, and antibiotics may be needed if the patient is neutropenic, febrile, or otherwise clinically abnormal. Treatment and hospitalization are dependent on the severity of illness.

The prognosis is good even without treatment as most TVTs will spontaneously regress within 6 months. Treatment usually results in a long-term control rate of 90%. However, in cases with distant metastasis, the prognosis is guarded.

Clinical Outcome
The dog was evaluated and found to be a good candidate for chemotherapy. Vincristine was administered at 0.6 mg/m² IV q7d for 7 weeks. There was no evidence of tumor regrowth at 6-month follow up.
